ABSTRACT

We present a simple scenario where the formation of galactic bulges was regulated by the dark halo gravity and regulated the growth of the central supermassive black hole. Assuming the angular momentum is low, we suggest that bulges form in a runaway collapse due to the "gravothermal" instability once the central gas density or pressure exceeds certain threshold (Xu & Zhao 2007). We emphasize that the threshold is nearly universal, set by the background NFW dark matter gravity $g_{DM} \sim 1.2 \times 10^{-8} \text{ cm sec}^{-2}$ in the central cusps of halos. Unlike known thresholds for gradual formation of galaxy disks, we show that the universal "halo-regulated" star formation threshold for spheroids matches the very high star formation rate and star formation efficiency shown in high-redshift observations of central starburst regions. The starburst feedback also builds up a pressure shortly after the collapse. This large pressure could both act outward to halt further infall of gas from larger scale, and act inward to counter the Compton-thick wind launched from the central black hole in an Eddington accretion. Assuming the feedback balancing inward and outward forces, our scenario naturally gives rise to the black hole-bulge relationships observed in the local universe.

1. INTRODUCTION

It is now widely believed that the violent star formation triggered by the merger of gas-rich galaxies is related to the formation of the galactic spheroidal component in the early Universe. The observational counterpart of these formation events may be represented by some intense star formation activity such as the Lyman break galaxies (LBGs) and submillimetre galaxies (SMGs) at $z \geq 3$ (Steidel et al. 1996; Smail et al. 1997), where the star formation rate could be as high as $\sim 1000 M_{\odot} \text{ yr}^{-1}$. These observed star-forming galaxies are just the progenitors of the spheroid-dominated galaxies in the local Universe. Their extremely high star formation rate implies that a large amount of gas turns into stars in a relatively short timescale, and the star formation efficiency (SFE) associated with these extreme situations are also very high (30 – 100%), much higher than the SFE inferred by the Schmidt-Kennicutt star formation law in the nearby disk galaxies and starburst galaxies (Kennicutt 1998). It has been proposed that there may be two different star formation modes for the disk and the spheroidal component respectively (Silk 2005). In the disk mode, the gravitational instability (Kennicutt 1989) and the porosity (Silk 1997) regulated mechanisms can keep the disk star formation rate and SFE from raising too high; in the spheroid mode, the star formation may be triggered by the bar instability in relatively less massive galaxies (Combes et al. 1990; Hasan, Pfenninger & Norman 1993; Wyse 2004); however, there is a lack of detailed models for the star formation in the massive spheroid component where a self-regulated mechanism is probably absent. So it has been suggested that the star formation may proceed in a maximum way during the formation of

galactic bulges (Elmegreen 1999).

Many evidences also show that the growth of supermassive black hole (SMBH) in galactic center is closely related to the star formation activity (Alexander et al. 2003; Heavens et al. 2004; Page et al. 2004). The similarity in the comoving space density between the star-forming galaxies and quasars offers strong proof for such a causal connection (Cattaneo & Bernardi 2003; Page et al. 2004; Stevens et al. 2004). The tight relationship of the black hole (BH) mass with the bulge velocity dispersion (Ferrarese & Merritt 2000; Gebhardt et al. 2000; Tremaine et al. 2002) and the bulge mass (Magorrian et al. 1998; McLure & Dunlop 2002; Marconi & Hunt 2003) also reveals such apparent association. On the other hand, observations of some starburst galaxies and bright quasars have shown clear evidences of outflows (Pettini et al. 2000; Adelberger et al. 2003; Pounds et al. 2003). This indicates that the mechanical feedback may play an important role in galaxy evolution and BH growth. Many previous discussions have emphasized that the central BH can interact with the surrounding environment in a self-regulated way (Silk & Rees 1998; Haehnelt, Natarajan, & Rees 1998; Blandford 1999; Fabian 1999; King 2003; Wyithe & Loeb 2003; Murray et al. 2005; Begelman & Nath 2005). All these models are based on an "outward" nuclear feedback scenario and are essentially similar; they differ only in whether the energy deposition or the momentum deposition dominates. All these models lead remarkably to the BH-bulge relation. Nevertheless, few of these studies carefully considered the star formation activity during the formation of the spheroid component and its relation with the BH growth even though we know it is important.

Therefore, it seems still worth to revisit more details of

this topic.

The motivation of this paper is to link several physical phenomena mentioned above, and explain them coherently. In this paper, we will present a simple analytical model to describe the star formation during the formation of the spheroidal component and the possible connection between the central starburst and the BH's growth. We show that the isothermal gas sphere embedded in a NFW dark matter halo becomes unstable at some critical radius once the ratio of the central gas pressure to the dark matter pressure exceeds certain threshold value, and the gas within this critical radius (maximum stable gas mass) will collapse and trigger the central starburst. Intense star formation accompanies strong star-forming feedback which plays an important role in resisting the gravity at large scale; while at small scale, the inward star forming feedback is introduced to connect the starburst region and the nuclear region by virtue of the theoretical and observational considerations. We also show that the BH's growth is confined and regulated by the inward star-forming feedback. Based on such inward star forming feedback scenario, the BH-bulge relations are naturally derived, which well match with the observations. We also show that the narrow range of the starburst duration and the dust-torus structure in AGNs can be explained under the same scenario.

The paper is organized as follows. In §2 we first discuss the density profile of the background dark matter potential and the isothermal gas sphere, then discuss the stability criterion of the isothermal gas sphere embedded in the dark matter background in detail. In §3 we describe the effects of the star-forming feedback and make a detail description of the so-called "halo-regulated" star formation mode. We discuss the effect of the inward star forming feedback and the obscured BH's growth in §4, and eventually obtain the BH-bulge relations in this section. We present some discussions in §5 and the main conclusions in §6.

2. GRAVOTHERMAL INSTABILITY AND PROTOGALAXY COLLAPSE

Following (Xu & Zhao 2007, hereafter XZ), we model the protogalaxy as an isothermal gas sphere embedded in the central r^{-1} cusp region of the dark matter potential, adopting the NFW density distribution for the dark matter (Navarro, Frenk & White 1997). The dark matter density profile is given by

$$\rho_{NFW}(r) \approx \Pi r^{-1}, \quad \Pi \equiv 130 M_{\odot} \text{pc}^{-2} M_{v,12}^{0.07} \zeta_c(z), \quad (1)$$

where $M_{v,12} = M_{vir}/10^{12} M_{\odot}$ and M_{vir} is the virial mass of the halo, $\zeta_c(z) \approx [0.3 + 0.7(1+z)^{-3}]^{2/3} \times 0.58[\ln(1+c) - c/(1+c)]$ where $c \approx 13.4 M_{v,12}^{-0.13} (1+z)^{-1}$ is the concentration parameter (Bryan & Norman 1998; Barkana & Loeb 2001; Bullock et al. 2001). Such a dark matter distribution produces almost a constant gravity

$$g_{DM}(r) = \frac{GM_{DM}(r)}{r^2} = 2\pi G\Pi \sim 1.2 \times 10^{-8} \text{cm sec}^{-2}. \quad (2)$$

After the baryons entering the dark matter halo, they will be shock-heated to the virial temperature. Then they will cool and settle into the core region of the dark

halo in gaseous form. If we assume the angular momentum is low, an isothermal spherical structure will be built in the core region of dark matter. Because there is large amounts of gas accumulating in the central region, the self-gravity of the gas sphere is not negligible. The combined gravity from the gas sphere itself and the background dark matter potential balances with the gas pressure. So we have the hydrostatic equilibrium equation in the inner region

$$\frac{\sigma^2}{\rho} \frac{d\rho}{dr} = -\frac{G(M_{gas} + M_{DM})}{r^2} = -\frac{G \int (\rho + \Pi r^{-1}) 4\pi r^2 dr}{r^2}, \quad (3)$$

where $\rho(r)$ is the gas density and σ is the velocity dispersion. The boundary conditions to be satisfied at the center $r = 0$ are

$$\rho(0) = \rho_0, \quad \frac{d\rho}{dr} = -\frac{2\pi\Pi G\rho_0}{\sigma^2}, \quad (4)$$

where ρ_0 is the central density. Once ρ_0 and σ are given, the gas density and mass profile under the hydrostatic equilibrium can be totally determined.

The stability of gas sphere embedded in a background potential was first investigated by Spitzer (1942), who pointed out that there is a maximum stable gas mass for a given temperature with a background potential of stars. A more recent sophisticated calculation was provided by Elmegreen (1999). He directly integrated the hydrostatic equilibrium equations for a mixture of the cold gas and dark matter. The equilibrium equations are $dP_{gas}/dr = \rho_{gas}g$ for gas and $dP_{DM}/dr = \rho_{DM}g$ for dark matter. The gravitational acceleration g comes from the both components and can be determined by the Poisson equation: $\nabla \cdot g = -4\pi G(\rho_{gas} + \rho_{DM})$. He used various density profile for gas and dark matter in his calculations, involving different central gas density. He found that there is no solution satisfying the equations if the ratio of the central gas density to the central dark matter density is larger than certain threshold value. Above such threshold value, any additional mass added to the combined components of gas and dark matter will make the whole system unstable. These two studies share common feature of finding a maximum gas mass from the hydrostatic or virial equilibrium equations. If the cumulated gas mass is larger than the maximum one, the gas pressure can not support the combined gravity from the sphere itself and the background dark matter, the sphere will inevitably collapse. So such instability is mainly affected by the "external" fluctuations. In another words, the equilibrium sphere will always keep in equilibrium unless there is additional mass from the outside added into the system.

The idea of XZ is similar but they emphasize the role of the so-call "gravothermal" instability: consider an isothermal gas sphere with fixed enclosed mass. A tiny compression of the sphere will decrease the volume and increase the density everywhere. The isothermal gas sphere would be stable with the density increasing everywhere at the same time, because the pressure will increase everywhere to push back the decreasing volume, balancing the increased gravity. However, if the density increases at the center, but is reduced at some large radii, the isothermal gas in the reduced pressure region can not support the gravity, and the region is unstable. In another words, the onset of instability is still possible

even if there is no additional mass added to the system. Actually, this is a thermodynamic type of instability which originates from the negative specific heat brought by the self-gravity of the sphere. The gravothermal instability of the pressure-bounded isothermal sphere has been investigated by many authors (Bonnor 1956; Lynden-Bell & Wood 1968; Lombardi & Bertin 2001). It is suggested that there is a threshold density contrast between the center and the edge, above which the system will become unstable. For the isothermal sphere embedded in a background potential, the background potential provides an additional inward force which is much like the external pressure in the pressure-bounded isothermal sphere. However, it has not been seriously considered. Using the variation method to investigate the problem, XZ have derived the exact stability criterion for the isothermal sphere with a background NFW potential. The criterion for the gas sphere to keep stable is

$$p_0 \equiv \rho_0 \sigma^2 \leq 31 p_{DM,0} \quad (5)$$

where p_0 is the central gas pressure and

$$p_{DM,0} = 4\pi G \Pi^2 \quad (6)$$

is the central dark matter pressure. XZ find that the instability starts at a critical radius $r_c \approx \sigma^2 / 2.2\pi \Pi G$, inside which the enclosed gas mass is

$$M_{g,max} = 1.78 \times 10^{11} \sigma_{200}^4 M_{v,12}^{-0.07} \zeta_c(z)^{-1} M_\odot. \quad (7)$$

XZ suggest that there is a threshold of the gas mass $M_{g,max}$ to collapse and trigger rapid star formation. It is reasonable to consider that the bulge formation just originates from such a gas collapse when the stability criterion Eq. (5) is violated. The gas that collapsed due to self-gravity is the direct material source for the bulge formation.

3. THE OUTWARD STAR FORMING FEEDBACK DURING THE BULGE FORMATION

In this section we will discuss the effects of the star-forming feedback. First, we will give a brief description to the star-forming feedback in starburst galaxies; Then we describe the so-called "halo-regulated" star formation mode by considering the effects of star-forming feedback. We note that many conclusions inferred from such star formation mode are consistent with recent observations. We point out that such mode is not only expected theoretically, but also actually exists in some extreme starburst regions.

3.1. The effects of star-forming feedback

When the central gas density exceeds the critical value, the collapse will compress the gas sphere and enhance the gas density. The squeezed gas is capable to form molecular clouds and eventually form stars inside the clouds, and a large amount of the gas accumulating in the central region will trigger the central starburst. Vigorous star formation activities will inevitably lead to strong star forming feedback. Here we mainly focus on two primary sources of star forming feedback: radiation pressure and supernovae. We know that the UV radiation can be absorbed by the dust efficiently, so the radiation pressure of the newly formed stars becomes important if the optical depth to the dust τ_{Dust} can reach the unity.

Actually, observations have shown that there are a large amount of dusts in the local and distant starburst galaxies (Lehnert & Heckman 1996; Sanders & Mirabel 1996; Adelberger & Steidel 2000). They should be produced by the supernovae rather than the AGB stars because of the relatively short duration of the starbursts. For a large star formation rate, the timescale for supernovae to reach $\tau_{Dust} \approx 1$ can be very short in comparing with the starburst duration (Murray et al. 2005). The momentum deposition rate of radiation pressure can be expressed as $\dot{P}_{rp} = \epsilon \dot{M}_* c$, where $\dot{M}_*$ is the star formation rate, ϵ is the efficiency of converting mass to energy in starbursts, and $\epsilon \approx 10^{-3}$ for a Salpeter IMF according to some starburst models (Leitherer et al. 1999). Here we assume that the star formation rate is proportional to the gas mass $M_{c,max}$ and inversely proportional to the dynamical time scale t_{dyn} ,

$$\dot{M}_* = \eta \frac{M_{g,max}}{t_{dyn}}, \quad (8)$$

where η is the star formation efficiency and $t_{dyn} \approx \sigma / (3.5\pi G \Pi)$ is the dynamical time scale.

On the other hand, the supernova remnants (SNRs) will quickly radiate their thermal energy when they propagate in the dense environment such as the central gas reservoir for starbursts, and enter the momentum driven phase (Monaco 2004). For a typical value, the net momentum deposited by supernovae has approximately the same order as that deposited by the radiation pressure (Murray et al. 2005). The whole momentum deposition rate can be written as

$$\dot{P} = \dot{P}_{rp} + \dot{P}_{sn} = \xi_m \epsilon \dot{M}_* c, \quad (9)$$

where $\xi_m = 1 + \dot{P}_{sn} / \dot{P}_{rp}$ is assumed of order of unity in our model.

3.2. The halo-regulated star formation

Gas in the inner region has higher density and shorter dynamical time, so the star formation feedback should be stronger there than in the outer region. The total net star-forming feedback is outward at large scale (however, we must bear in mind that it may not be the case at very small scale, see discussions in §4), and the outward star-forming feedback can be regarded as the anti-gravitational source. Because the gas density in the starburst region is extremely high and the cooling of the gas is very efficient, the heating effect is neglected. The star-forming feedback could increase the potential energy of the whole system so as to help the system back to the virial equilibrium. We assume that the whole system re-virialize at radius r' . According to the above argument, we expect that the additional inward drag provided by the background dark matter potential is compensated by the outward star-forming feedback. Namely, we should have

$$\int \xi_m \epsilon \dot{M}_* c dr' = \xi_m \epsilon \dot{M}_* c r' = \pi \Pi G M_{c,max} r', \quad (10)$$

where the left side and right side of Eq. (10) denote the equivalent potential energy of the star forming feedback and the potential energy from the dark matter background. Here we use the fact that the quantity $\xi_m \epsilon \dot{M}_* c$ is independent on the radius r' and we assume that the

stars form deeply inside the molecular cloud and don't appear optically bright during the main epoch of star formation. Eq. (10) can also be directly written as

$$\xi_m \epsilon \dot{M}_* c = \pi \Pi G M_{c,max}. \quad (11)$$

The above equation suggests that the star formation rate of the central starburst region, being directly related to the total collapse gas mass $M_{c,max}$, is constant if $M_{c,max}$ is fixed. If the star formation rate increases slightly, the left side of Eq. (11) will be larger than the right side, and the system is puffed up due to the star-forming feedback, and the star formation rate will therefore decrease again to make the whole system return to the equilibrium state. So Eq. (11) requires that the star formation activity in the central starburst region is regulated by the gravity from the dark matter background. Such "halo-regulated" star formation mode is very different from that in the nearby disk galaxies. Here we calculate some parameters based on this mode in order to compare them with the observations.

Using Eq. (8) to eliminate $\dot{M}_*/M_{c,max}$ in Eq. (11), from the expression of t_{dyn} in §3.1 we obtain the star formation efficiency as

$$\eta = \frac{\sigma \pi}{3.11 \xi_m \epsilon c} = 0.68 \sigma_{200} \xi_m^{-1} \epsilon_3^{-1}, \quad (12)$$

where $\epsilon_3 = \epsilon/10^{-3}$. Substituting Eq. (7) into Eq. (8) and using Eq. (12), we obtain the threshold star formation rate in the central starburst region as

$$\dot{M}_* = \frac{\sigma^4}{1.1 G \xi_m \epsilon c} \approx 1000 \sigma_{200}^4 \xi_m^{-1} \epsilon_3^{-1} M_\odot yr^{-1}, \quad (13)$$

and the star formation timescale

$$t_* = \frac{t_{dyn}}{\eta} = \frac{\xi_m \epsilon c}{\pi \Pi G} \approx 1.0 \times 10^8 \xi_m \epsilon_3 M_{v,12}^{-0.07} \zeta_c^{-1}(z) yr. \quad (14)$$

It is interesting to note that the star formation efficiency (SFE) as well as the star formation rate (SFR) are closely related to the velocity dispersion. The large the velocity dispersion is, the higher SFR and SFE are. The result implies that there is higher fraction of gas converting into stars in more massive galaxies (eg. giant elliptical) and the high redshift SMGs observations show that it may be just the case (Alexander et al. 2005).

4. THE INWARD STAR FORMING FEEDBACK AND THE OBSCURED BLACK HOLE GROWTH

Because the star formation is unlikely to proceed efficiently at very small scales (e.g. galactic nuclei), the starburst region can not be regarded as a point source comparing with the central BH, and the momentum feedback from starbursts should transport in two directions: the outward one to resist the gravity and the inward one to drive some part of gas to feed the BH. If the initial BH mass is not very large ($\leq 10^6 M_\odot$), the inflow gas is sufficient for the BH to accrete at Eddington accretion rate for a long time. Initially, the feedback exerting on the surrounding gas of the BH can't balance the inward feedback from the starburst region, the BH will hide in a gas shell (see Figure 1 for a cartoon view) and be optically thick to the optical and UV radiations. Hence the

main growth phase of the BH should be obscured (so-called "pre-quasar" phase), which is consistent with the SMG observations (Alexander et al. 2005).

The feedback from BH will be stronger as the BH grows bigger. Because of the obscured growth environment and the possible high accretion rate, the momentum flux may transport outwards via a Compton-thick wind launched from the BH's accretion disk. If we assume that the covering factor of the wind is large enough, the net momentum flux rate deposited in the wind driven by the radiation pressure from BH can be expressed as (King & Pounds 2003)

$$\dot{P}_{wind} = \dot{M}_{out} v_{out} = \frac{2L_{EDD}}{c} = \frac{8\pi G M_{BH}}{\kappa}, \quad (15)$$

where $\dot{M}_{out}$ is the outflow rate and v_{out} is the outflow velocity. Once the balance between the inward starburst feedback and outward BH feedback is achieved, we have

$$\dot{P}_{wind} = \xi_m \epsilon \dot{M}_* c, \quad (16)$$

then the BH's feedback is large enough to halt the further gas supply, so we can say that a BH will end its main growth phase after Eq. (16) is satisfied. Based on the argument in §2, the bulge mass is approximated as $M_{c,max}$. Using Eqs. (11), (15) and (16), the ratio of BH mass to bulge mass can be expressed as

$$\frac{M_{BH}}{M_{bulge}} = \frac{\kappa \Pi}{8} \approx 1.4 \times 10^{-3} M_{v,12}^{0.07} \zeta_c(z). \quad (17)$$

Combining Eq. (17) with (7), we can also derive the $M_{BH} - \sigma$ relation

$$M_{BH} \approx \frac{\kappa \sigma^4}{10 \pi G^2} = 1.8 \times 10^8 \sigma_{200}^4 M_\odot. \quad (18)$$

The above results are surprisingly consistent with the local observations (Magorrian et al. 1998; McLure & Dunlop 2002; Marconi & Hunt 2003; Tremaine et al. 2002).

5. DISCUSSIONS

The so-called "halo-regulated" star formation mode requires the additional gravity from dark matter to regulate the SFR and SFE to a very high level (although they may drop at the late stage). It means that a large fraction of gas is converted into stars in a relatively short timescale without being dispersed or blown out. The SFR is much higher than that in normal disk galaxies inferred from the Kennicutt Law, but is consistent with the observations of high-redshift starburst galaxies (Solomon & Vanden Bout 2005) and some small scale star formation phenomena (e.g. SFE during the formation of the bound cluster (Lada, Margulis & Dearborn 1985)). This convinces us that such star formation mode actually works in extreme environments, such as the central starburst region at high redshift, which is very different from that of local universe. We also note that the star formation timescale only has weak dependence with the redshift (see Eq. (14)), and is independent on the mass of the galaxy roughly keeping the same over a large redshift range. It may explain the narrow range ($100 \sim 300 Myr$) of the starburst duration inferred from Faber-Jackson relation (Murray et al. 2005).

Many previous momentum driven models argue that when the BH grows big enough it can blow most of the

gas away to end its growth (King 2003; Murray et al. 2005; Begelman & Nath 2005). The main difference between our model and these previous models is that in our model the inward star forming feedback plays important role in regulating the BH mass. Simulation shows that the inward star forming feedback transports most momentum but little gas into the nuclear region (Mori, Ferrara & Madau 2002). Hence, the gas obscuring the BH is much less than the total amount of gas in the starburst region. According to Eq. (11), we find that the gravity of the gas in the nuclear region is much smaller than the inward star forming feedback. So it is reasonable to reckon that the BH is confined by the inward star forming feedback rather than to drive large scale outflow. The BH will end its growth once the feedback from BH is big enough to balance the inward star forming feedback, and the BH-bulge relation is naturally derived from the final balance condition (see Eq.(16)). There are two interesting points to note: first, our derived $M_{BH} - \sigma$ relation (see Eq.(18)) is independent of the parameter of the detailed star formation process; second, the derived mass ratio between the BH and bulge is only related to some properties of the background dark matter density profile Π , independent of the progenitor's gas fraction or the total gas mass in the nuclear region. We think that it is all because that the "halo-regulated" star formation mode makes the star formation activity as an equivalent effect as the dark matter gravitational effect. We also find that our derived $M_{BH} - \sigma$ relation (see Eq.(17)) has no evolution with the redshift, which is consistent with many previous models and the observations out to the median redshift (Shields et al. 2003; Wu 2007), while the $M_{BH} - M_{bulge}$ relation has weak dependence on the redshift. At high redshift $z \sim 3$, $M_{v,12}^{0.07} \zeta_c(z)$ change by a factor $10^{0.14} \times 0.5^{2/3} \times 1.4 \sim 1.3$; assuming M_{vir} was ten times smaller at high redshift. From Eq. (17) we can see that the total effect is: the M_{BH}/M_{bulge} ratio is roughly the same, only with small scatters (at $z \leq 3$). The result implies that at least some part of the scatter of the $M_{BH} - M_{bulge}$ is intrinsic.

Furthermore, the remaining angular momentum of the dusty gas surrounding the BH during its obscured growth phase may not be negligible at very small scale. This angular momentum could make the configuration of the shrouded gas deviate from the ideal sphere, and distribute more like a "hamburger". Therefore, once the BH grows large enough, the wind from the direction of angular momentum will first "crush the cocoon" and show an optically bright phase (see Figure 2 for a cartoon view). Such a scenario offers a natural explanation to the formation of the dust-torus in AGNs, which is considered as an important part in the AGN unification model (Antonucci

1993). We also predict that the dust in the dust-torus of AGN may originate from the outside starburst region, and the covering angle of the dust torus may closely relate to the BH mass. This tentative result needs to be confirmed by the future observations.

6. CONCLUSIONS

Here we itemize the conclusions which we have derived in this paper:

1. We suggest that bulges form in a "monolithic" collapse and subsequent rapid star formation. We argue that such runaway collapse is due to the gravothermal instability. The isothermal sphere with a NFW dark matter background becomes unstable when the central gas pressure is about 30 times larger than the central dark matter pressure. The collapsed gas will result in vigorous star formation activities and is the direct material source of the bulge formation.

2. The squeeze and compression help the gas to form molecular clouds, then many stars form in those clouds during a relatively short timescale and the central starburst is triggered. Intense starburst brings strong star forming feedback, having the $M_{g,min}$ and r_c in hand and assuming the momentum driven mechanism dominates, we calculate the star formation rate and the related star forming feedback. We argue that the star forming feedback serves as the source to resist the gravity and will finally help the system return to equilibrium and halt the gas collapse. Hence, the "halo-regulated" star formation mode is required and we find such star formation mode can well match the high redshift starburst observations.

3. We reckon that the inward star forming feedback should exist to conserve the local momentum and to connect the outside starburst region and nuclear region. The inward star forming feedback can push large amounts of gas to the central region to obscure and confine the central BH (if the BH mass is not so large) and the BH system may appear as a "pre-quasar". We suggest that the BH growth is just regulated by the inward star forming feedback. We give the condition for the BH to end its growth is that the compton-thick disk wind balances the inward star forming feedback. Based on this we derive the BH-bulge relations which are well consistent with the local observations.

The authors thank Fukun Liu and Shude Mao for helpful discussions and the anonymous referee for helpful suggestions. XBW acknowledges the support of NSFC Grant (No.10473001 and No.10525313) and the RFDP Grant (No.20050001026).

FIG. 1.— A cartoon which describes the obscured growth of the central BH at the early growth stage. The shaded part is starburst region, which generates momentum feedback in two directions if there are enough dusts. The outward one resists the gravity while the inward one regulates the growth of the BH. Because the mass of BH is small at early stage, the feedback from BH can't balance the inward feedback from the starburst. The push of the inward starburst feedback combining with the remained angular momentum force the gas to form the above shape. The BH will hide in the thick gas shell and can not be seen in optical band.

FIG. 2.— A cartoon which describes the stage after the main (obscured) growth stage of the central BH. Till the feedback from the BH balances the inward feedback from the starburst, compton-thick wind from BH can easily "crush the cocoon" in the direction of the angular momentum and form the torus-shape. It may explain the formation of the dust-torus in many AGNs.
